Abstract

In this paper, we analyze local search heuristics for the k-median and facility location problems. We define the *locality gap* of a local search procedure for a minimization problem as the maximum ratio of a locally optimum solution (obtained using this procedure) to the global optimum. For k-median, we show that local search with swaps has a locality gap of 5. Furthermore, if we permit up to p facilities to be swapped simultaneously, then the locality gap is $3 + 2/p$. This is the first analysis of a local search for k-median that provides a bounded performance guarantee with only k medians. This also improves the previous known 4 approximation for this problem. For uncapacitated facility location, we show that local search, which permits adding, dropping and swapping a facility, has a locality gap of exactly 3. This improves the bound of 5 given by Korupolu et al. We also consider a capacitated facility location problem where each facility has a capacity and we are allowed to open multiple copies of a facility. For this problem we introduce a new local search operation which opens one or more copies of a facility and drops zero or more facilities. We prove that this local search has a locality gap between 3 and 4.

1 Introduction

The problem of locating facilities in a manner so that they can effectively serve a set of clients has been the subject of much research. While one could consider fairly general measures of effectiveness of a set of locations in serving the clients, one measure that is typically used is the distance between the client and the facility that is serving it. Since by opening a lot of facilities, we can be near every client, it also makes sense to take into account the number of facilities opened in judging the quality of a solution. These two measures, typically referred to as the service cost and the facility cost, can be combined in many ways to obtain interesting variants to the general facility location problem. For instance, in *k-median* we require that at most k facilities be opened and the total service cost,

measured as the sum of the distances of each client to the nearest open facility, be minimum. Instead of setting a limit on the total number of facilities that could be opened, we sometimes associate with every facility, a cost of opening that facility. The facility cost of a solution is then the sum of the costs of the facilities that are opened and the quality of the solution is measured by the sum of the facility and service costs. This, in fact, is the classical *facility location problem*. Note that in this setting the facility costs need not be same and would, in general depend on the location at which the facility is being opened. A generalization of the classical facility location problem arises when we associate a capacity with each facility, which measures the maximum number of clients that the facility can serve. Further variants of this *capacitated facility location* (CFL) problem arise when we bound the number of facilities that can be opened at a certain location. Thus in k-CFL, we can open at most k facilities at any location.

Local search techniques have been very popular as heuristics for hard combinatorial optimization problems. The 1-exchange heuristic by Lin and Kernighan [12] for the metric-TSP remains the method of choice for practitioners. However, most of these heuristics have poor worst-case guarantees and very few approximation algorithms that rely on local search are known. Köneman and Ravi [11] use local search algorithms for degree-bounded minimum spanning trees. Chandra et al. [2] show an approximation factor of $4\sqrt{n}$ for 2-exchange local search heuristic for euclidean traveling salesman problem. Khuller et al. [10] give a local search approximation algorithm for finding a cotree[1] incident on minimum number of vertices. Local search has also been used for set packing problems by Arkin and Hassin [1]. Here, we provide worst-case analysis of local search algorithms for facility location problems.

For an instance I of a minimization problem, let $\texttt{global}(I)$ denote the global optimum and $\texttt{local}(I)$ be the locally optimum solution provided by a certain local search heuristic. We call the supremum of the ratio $\texttt{local}(I)/\texttt{global}(I)$, the *locality gap* of this local search procedure. For 1-CFL with uniform capacities, Korupolu et al. [14, 15] argued that any procedure that permits adding, dropping or swapping a facility has a locality gap of at most 8. Their analysis was subsequently refined and tightened by Chudak and Williamson [6] to yield a locality gap of at most 6. Pál et al. [13] present a local search algorithm for facility location with non-uniform hard capacities which yields a $9+\epsilon$ approximation. For the uncapacitated version, Korupolu et al. [14, 15] provide a bound of 5 on the locality gap when the only operations permitted are those of adding, dropping or swapping a facility. Charikar and Guha [3] introduced an operation which permits adding a facility and dropping many, and showed that this local search procedure has a locality gap of exactly 3. For k-median, Korupolu et al. [14, 15] gave a local search procedure which permitted adding, deleting and swapping facilities and gave a solution with $k(1+\epsilon)$ having a service-cost at most $3+5/\epsilon$ times the optimum k-median solution. Kanungo et al. [9] give a $9+\epsilon$ approximation by local search for the k-means problem in Euclidean metric.

A different approach to facility location was employed by Shmoys et al. [16] and Charikar et al. [17]. They formulated the problems as linear programs and rounded the optimum fractional solution to obtain a 3 approximation for the uncapacitated facility location(UFL) problem and a $6\frac{2}{3}$ approximation for k-median respectively. Jain and Vazirani [8] gave an alternate 3 approximation algorithm for UFL using the primal-dual schema. They also observed that k-median can be viewed as a Lagrange-relaxation of UFL and utilized this to give a 6 approximation algorithm for k-median. Charikar and Guha [3] improved this to a 4 approximation. Guha and Khuller [7] employed randomization to improve the approximation guarantee of UFL to 2.408. This was further improved to $(1+2/e)$ by Chudak [4] and finally to 1.728 by Charikar and Guha [3]. Similar ideas

[1] A cotree in a connected graph is a subset of edges that is the complement of a spanning tree.

were used by Chudak and Shmoys [5] to obtain a 3 approximation algorithm for ∞-CFL when the capacities are uniform. Jain and Vazirani [8] obtained a 4 approximation algorithm for ∞-CFL when the capacities were non-uniform by solving a related UFL problem using their primal-dual algorithm.

Our Results: In this paper, we analyze local search heuristics for three problems.

1. For k-median, we show that local search with single swaps has a locality gap of 5. This is the first analysis of local search for k-median that provides a bounded performance guarantee with only k medians. We also show that doing multiple swaps, that is, dropping at most p facilities and opening the same number of new facilities yields a locality gap of $3 + 2/p$. This improves on the 4 approximation algorithm for k-median by Charikar and Guha [3]. Our analysis of the locality gap is tight, that is, for an infinite family of instances there is a locally optimum solution whose service cost is nearly $(3 + 2/p)$ times that of the global optimum.

2. For UFL, we show that local search, which permits adding, dropping and swapping a facility, has a locality gap of 3. This improves the bound of 5 given by Korupolu et al. [14]. Again, our analysis of the algorithm is tight. Using standard scaling techniques [3] our algorithm can be improved to achieve a $1 + \sqrt{2} \approx 2.414$ approximation.

3. For ∞-CFL, we consider the setting when the capacities may be non-uniform and argue that local search, where the only operation permitted is to add multiple copies of a facility and drop zero or more facilities, has a locality gap of at most 4. As for UFL, we give a polynomial algorithm that uses `Knapsack` as a subroutine to search a subspace of adjacent solutions. We also show an instance where the polynomial time algorithm cannot find an adjacent solution of lower cost and which has cost 3 times the optimum. Again using scaling techniques [3] the algorithm can be improved to obtain a $2 + \sqrt{3} \approx 3.732$ approximation.

The paper is organized as follows. Section 2 introduces some notation. In Section 3, we prove a locality gap of 5 for the k-median problem when only single swaps are permitted; in Section 3.3, we show how the above analysis can be extended to argue a locality gap of $3 + 2/p$ when up to p facilities can be swapped simultaneously. Section 4 and Section 5 discuss the algorithms for UFL and ∞-CFL respectively. Section 6 concludes with some open problems.

2 Notation and Preliminaries

In the k-median and facility location problems, we are given two sets: F, the set of *facilities* and C, the set of *clients*. There is a specified *distance* $c_{ij} \geq 0$ between every pair $i, j \in F \cup C$. In these problems, the goal is to identify a subset of facilities $S \subseteq F$ and to serve the clients in C by the facilities in S, such that some cost function is minimized. The facilities in S are said to be *open*. The metric versions of these problems assume that the distances c_{ij} are symmetric and satisfy the triangle inequality.

A generic local search algorithm (Figure 1) can be described by a set of $\mathcal{S}$ of all feasible solutions, a cost function, $cost : \mathcal{S} \to I\!R$ and a neighbourhood structure $\mathcal{N} : \mathcal{S} \to 2^{\mathcal{S}}$. A solution $S \in \mathcal{S}$ is called *locally optimum* if $cost(S) \leq cost(S')$ for all $S' \in \mathcal{N}(S)$; the algorithm in Figure 1 always returns one such solution. The cost function and the neighbourhood structure $\mathcal{N}$ will be defined differently for different problems and algorithms.

To run this algorithm in polynomial time, we modify the step 2 of the algorithm as follows.

2. While $\exists\, S' \in \mathcal{N}(S)$ such that $cost(S') \leq (1 - \frac{\epsilon}{p(n,m)})cost(S)$,
   do $S \leftarrow S'$.

Algorithm `Local Search.`

1. $S \leftarrow$ an arbitrary feasible solution in $\mathcal{S}$.
2. While $\exists\, S' \in \mathcal{N}(S)$ such that $cost(S') < cost(S)$, do $S \leftarrow S'$.
3. return S.

Figure 1: A generic local search algorithm

Here $\epsilon > 0$ is a constant, $n = |F|$ is the number of facilities, $m = |C|$ is the number of clients and $p(n, m)$ is a polynomial in n and m. At any execution of the step 2, there will be at most a polynomial number of neighbours to be checked. Also during each local step, the cost of the current solution decreases by a factor of at least $\epsilon/p(n, m)$. If O denotes an optimum solution and S_0 denotes the initial solution, then the number of steps that the algorithm does is at most $\log(cost(S_0)/cost(O))/\log\frac{1}{1-\epsilon/p(n,m)}$. As $\log(cost(S_0))$ is polynomial in the input size and performing each step takes a polynomial time, this algorithm terminates in polynomial time. When the current solution is a locally optimum solution, we know that for every neighbour $S' \in \mathcal{N}(S)$,

$$cost(S') \;\geq\; (1 - \frac{\epsilon}{p(n, m)})\; cost(S) \tag{1}$$

To simplify the exposition, we work with the assumption that no neighbour $S' \in \mathcal{N}(S)$ has cost less than that of current solution, that is,

$$cost(S') \;\geq\; cost(S).$$

We will add at most $p(n, m)$ of such inequalities to conclude that $cost(S) \leq \alpha \cdot cost(O)$ for some $\alpha \geq 1$. Adding the corresponding original inequalities (1) implies that $cost(S) \leq \alpha(1 + \epsilon)cost(O)$. Thus our proof that a certain local search procedure has locality gap of at most α translates into a $\alpha(1 + \epsilon)$ approximation algorithm.

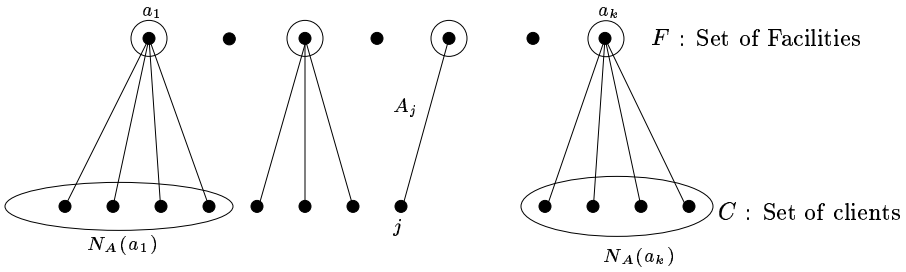

Figure 2: Illustration of neighbourhood and service costs

We use the following notations. Let S denote the output of the algorithm and O denote an optimum solution. Consider any solution A for the above problems. The cost of serving a client j, or the *service cost* of j, denoted by A_j, is the distance between j and the facility that serves it in A. For every open facility $a \in A$, we associate a neighbourhood $N_A(a)$, which is the set of clients in C that the facility a serves in the solution A (Figure 2). Thus, S_j and O_j denote the service costs of the client j in the solutions S and O respectively. Similarly, we associate neighbourhoods

$N_S(s)$, and $N_O(o)$ with each open facility $s \in S$, and $o \in O$. For a subset $A \subseteq S$ and $B \subseteq O$, let $N_S(A) = \bigcup_{s \in A} N_S(s)$ and $N_O(B) = \bigcup_{o \in B} N_O(o)$.

3 The k-median problem

In the k-median problem, we are given an input parameter k, $0 < k \leq |F|$. The problem is to identify a subset $S \subseteq F$ of at most k facilities and to serve the clients in C by the facilities in S such that the total service cost is minimized. Thus, if a client $j \in C$ is served by a facility $\sigma(j) \in S$, then we want to minimize $cost(S) = \sum_{j \in C} c_{\sigma(j)j}$. For a fixed S, serving each client by the nearest facility in S, minimizes this cost.

3.1 Local search with single swaps

In this section, we consider a local search using single-swaps. A swap is effected by closing a facility $s \in S$ and opening a facility $s' \notin S$, and is denoted by $\langle s, s' \rangle$. So $\mathcal{N}(S) = \{S - \{s\} + \{s'\} | s \in S, s' \notin S\}$. We start with an arbitrary set of k facilities and keep improving our solution with such swaps until we reach a locally optimum solution. The algorithm is described in Figure 1. We use $S - s + s'$ to denote $S - \{s\} + \{s'\}$.

3.2 The analysis

We now show that the local search procedure as defined above has a locality gap of 5. From the local optimality of S, we know that,

$$cost(S - s + o) \geq cost(S) \quad \text{for all } s \in S, o \in O \tag{2}$$

Note that even if $S \cap O \neq \emptyset$, the above inequalities hold. We combine these inequalities to show that, $cost(S) \leq 5 \cdot cost(O)$.

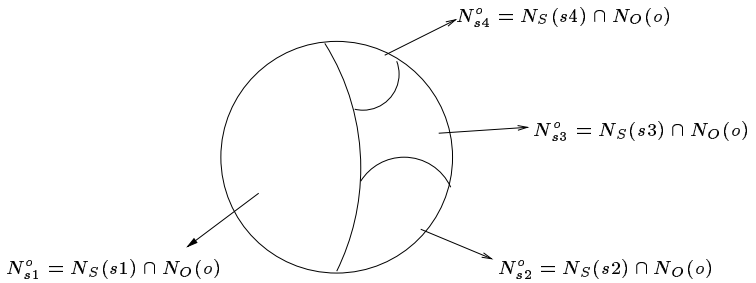

Figure 3: Partitioning $N_O(o)$

Consider a facility $o \in O$. We partition $N_O(o)$ into subsets $N^o_s = N_O(o) \cap N_S(s)$ as shown in Figure 3. We say that a facility $s \in S$ *captures* a facility $o \in O$ if s serves more than half the clients served by o, that is, $|N_S(s) \cap N_O(o)| > \frac{1}{2}|N_O(o)|$. It is easy to see that a facility $o \in O$ is captured by at most one facility in S. We call a facility $s \in S$ *bad* if it captures some facility in $o \in O$, and *good* otherwise. When a facility $s \in S$ is swapped out, we have to reassign all the clients served by s. Consider a facility $s \in S$ which does not capture $o \in O$. To help us reassign clients in such N^o_ss we define a 1-1 and onto function $\pi : N_O(o) \to N_O(o)$ satisfying the following property(Figure 4).

Property 3.1 *For all $s \in S$ and $o \in O$ such that, $|N_s^o| \leq \frac{1}{2}|N_O(o)|$, we have, $\pi(N_s^o) \cap N_s^o = \emptyset$.*

It is easy to see that such a mapping π exists. This function is considered only for the purpose of analysis.

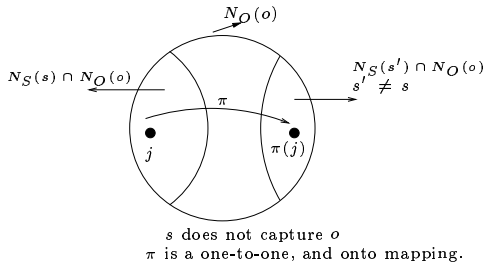

Figure 4: A matching π on $N_O(o)$

The notion of *captures* can be used to construct a bipartite graph $H = (S, O, E)$(Figure 5). The vertices of S are on one side, and vertices of O on the other. We add an edge between $s \in S$ and $o \in O$ if s captures o. It is easy to see that the degree of vertices in O is at most one, while the degree of vertices in S is bounded only by k. We call H as *capture graph*.

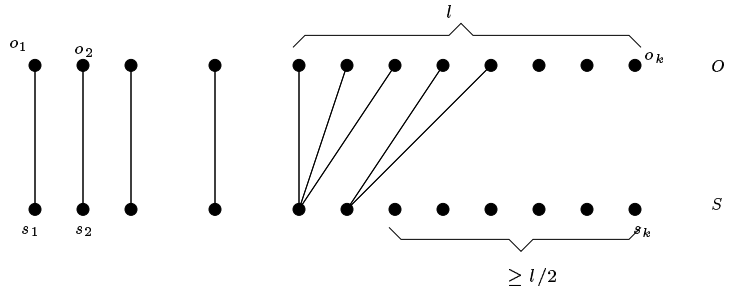

Figure 5: Capture Graph $H = (S, O, E)$

We now consider k swaps, one for each facility in O. If some bad facility $s \in S$ captures exactly one facility $o \in O$ then we consider the swap $\langle s, o \rangle$. These are vertices in S with degree one in *capture graph*. Suppose l facilities in S (and hence l facilities in O) are not considered in such swaps. These l facilities in S are either good or bad, and the bad facilities capture at least two facilities in O. Hence there are at least $l/2$ good facilities in S. Now, consider l swaps in which the remaining l facilities in O get swapped with the good facilities in S such that each good facility is swapped-out at most twice (Figure 6).

It is easy to verify that the swaps considered above satisfy the following properties.

1. Each $o \in O$ is swapped-in exactly once.
2. Each $s \in S$ is swapped-out at most twice.
3. If a swap $\langle s, o \rangle$ is considered, the facility s does not capture any facility $o' \neq o$.

This is because a facility in S that captures more than one facility in O is never swapped-out and a facility that captures exactly one facility in O is swapped only with the facility that it captures.

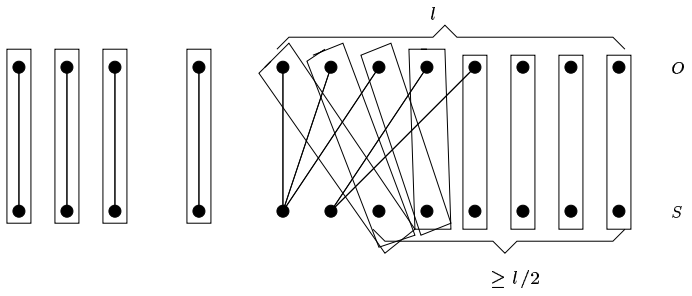

Figure 6: k swaps considered in the analysis

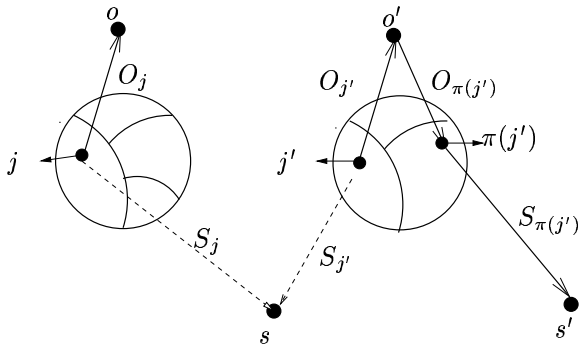

Figure 7: Reassigning the clients in $N_S(s) \cup N_O(o)$.

We now analyze these swaps by considering an arbitrary swap $\langle s, o \rangle$. We place an upper bound on the increase in cost due to this swap by reassigning the clients in $N_S(s) \cup N_O(o)$ to the facilities in $S - s + o$ as follows(Figure 7). The clients $j \in N_O(o)$ are now assigned to o. Consider a client $j' \in N_S(s) \cap N_O(o')$, for $o' \neq o$. As s does not capture o', we have $|N_S(s) \cap N_O(o')| \leq \frac{1}{2}|N_O(o')|$ and hence by the property of π, we have that $\pi(j') \notin N_S(s)$. Let $\pi(j') \in N_S(s')$. Note that the distance that the client j' travels to the nearest facility in $S - s + o$ is at most $c_{j's'}$. Also from triangle inequality, $c_{j's'} \leq c_{j'o} + c_{o\pi(j')} + c_{\pi(j')s'} = O_{j'} + O_{\pi(j')} + S_{\pi(j')}$. We can upperbound the service cost of the remaining clients by not changing their assignments. From inequality (2) we have,

$$cost(S - s + o) - cost(S) \;\geq\; 0$$

Therefore,

$$\sum_{j \in N_O(o)} (O_j - S_j) + \sum_{\substack{j \in N_S(s), \\ j \notin N_O(o)}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \geq 0 \tag{3}$$

As each facility $o \in O$ is swapped-in exactly once, the first term of the inequality (3) added over all the k swaps gives exactly, $cost(O) - cost(S)$. For the second term, we use the fact that each s is swapped-out at most twice. Also for any $j \in C$, as S_j is the shortest distance from j to a facility in S, we get, using triangle inequality, $O_j + O_{\pi(j)} + S_{\pi(j)} \geq S_j$. Thus the second term of

the inequality (3) added over all the k swaps is not greater than $2\sum_{j\in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j)$. But as π is 1-1 and onto mapping, $\sum_{j\in C} O_j = \sum_{j\in C} O_{\pi(j)} = cost(O)$ and $\sum_{j\in C}(S_{\pi(j)} - S_j) = 0$. Thus, $2\sum_{j\in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 4 \cdot cost(O)$. Combining the two terms we get, $cost(O) - cost(S) + 4 \cdot cost(O) \geq 0$. Thus we have the following theorem.

Theorem 3.1 *A local search procedure for the metric k-median problem with operations defined as, $\mathtt{op}(S) := S - s + s'$ for $s \in S$ and $s' \notin S$, has a locality gap at most 5.*

The above algorithm and analysis extend very simply to the case when the clients $j \in C$ have arbitrary demands $d_j \geq 0$ to be served.

3.3 Local search with multi-swaps

In this section, we generalize the algorithm in Section 3 to consider multi-swaps in which up to p facilities could be swapped simultaneously. The operation $\mathtt{op}$ is now defined as,

$$\mathtt{op}(S) := (S \setminus A) \cup B \quad \text{for } A \subseteq S \text{ and } B \subseteq F \setminus S \text{such that } |A| = |B| \leq p$$

This swap will be denoted by $\langle A, B\rangle$, and we prove that the locality gap of the k-median problem with respect to this operation is exactly $(3 + 2/p)$.

3.4 Analysis

We extend the notion of capture as follows. For a subset $A \subseteq S$, we define,

$$capture(A) = \{o \in O : |N_S(A) \cap N_O(o)| > |N_O(o)|/2\}$$

It is easy to observe the following properties.

1. If $X, Y \subseteq S$ are disjoint then $capture(X)$ and $capture(Y)$ are disjoint.
2. If $X \subset Y$ then $capture(X) \subseteq capture(Y)$.

We now partition S into sets $A_1, A_2, \ldots, A_r$ and O into sets $B_1, B_2, \ldots, B_r$ such that

1. $\forall i : 1 \leq i \leq r-1$, $|A_i| = |B_i|$ and $B_i = capture(A_i)$. It follows that, $|A_r| = |B_r|$.
2. $\forall\ A_i, 1 \leq i \leq r-1$ will have exactly one bad facility.
3. The set A_r contains only good facilities.

A procedure to define such a partition is defined in Figure 8.

Claim 3.1 *The procedure defined in Figure 8 terminates with a partition of S, O, satisfying the properties listed above.*

Proof. The condition of the while loop in step 4, and the assignment in step 5 of our procedure maintains the invariant that $|S| = |O|$. The steps 3, and 4.2 of our procedure maintain the invariant that, $\forall i : 1 \leq i \leq r-1$, $B_i = capture(A_i)$, and steps 2, 4.1 maintain the property that each A_i, $1 \leq i \leq r-1$ has exactly one bad facility. Each execution of the while loop in step 4 of our procedure terminates because, before each execution of the step 4.1, the invariant $|A_i| < |B_i|$ is

procedure Partition;

$i = 0$;

while $\exists$ a bad facility **do**

$\{iteration\ i\ \}$

1. $i = i + 1$;

2. $A_i \leftarrow \{b\}$ where $b \in S$ is any bad facility;

3. $B_i \leftarrow capture(A_i)$;

4. while $|A_i| \neq |B_i|$ **do**

4.1. $A_i \leftarrow A_i \cup \{g\}$ where $g \in S \setminus A_i$ is any good facility;

4.2. $B_i \leftarrow capture(A_i)$;

5. $S \leftarrow S \setminus A_i$;

$O \leftarrow O \setminus B_i$;

$A_r \leftarrow S$;

$B_r \leftarrow O$;

end.

Figure 8: A procedure to define the partitions

true, and this together with the fact that $|S| = |O|$ implies that there is always a good facility in $S \setminus A_i$.

■

Now we define the swaps as follows. If for some i, we have, $|A_i| = |B_i| \leq p$ then we consider the swap $\langle A_i, B_i \rangle$. From the local optimality of S we have the following inequality.

$$cost((S \setminus A_i) \cup B_i) - cost(S) \geq 0$$

Note that even if $A_i \cap B_i \neq \emptyset$ or $S \cap B_i \neq \emptyset$, the above inequality continues to hold.

If on the other hand, for some i, we have, $|A_i| = |B_i| = q > p$, we swap each facility $o \in B_i$ with each of the $q - 1$ *good* facilities $s \in A_i$. Note that if $i \neq r$, there are exactly $q - 1$ good facilities in A_i and for $i = r$, we select any $q - 1$ out of the q good facilities in A_r. For each such swap $\langle s, o \rangle$, we have,

$$cost(S - s + o) - cost(S) \geq 0$$

We add such $q(q-1)$ inequalities and multiply them by a factor $1/(q-1)$. Thus, each good facility in A_i is considered in at most $q/(q-1) \leq (p+1)/p$ swaps.

For each facility $o \in O$, $N_O(o)$ is partitioned as follows.

1. Let i, $1 \leq i \leq r$, be such that $|A_i| \leq p$, so that the swap $\langle A_i, B_i \rangle$ was considered above. We consider the part, $p_{A_i} = N_S(A_i) \cap N_O(o)$.

2. Let i, $1 \leq i \leq r$, be such that $|A_i| > p$. We consider the parts $p_s = N_S(s) \cap N_O(o)$ for each $s \in A_i$.

Now, for each facility $o \in O$, we consider a 1-1 and onto mapping $\pi : N_O(o) \rightarrow N_O(o)$ with the following property.

Property 3.2 *For all parts $p = p_{A_i}$ or p_s defined above, such that $|p| \leq \frac{1}{2}|N_O(o)|$, we have, $\pi(p) \cap p = \emptyset$.*

As this condition is imposed only on the parts that have at most half the number of clients in $N_O(o)$, such a mapping π exists. While doing a swap $\langle A_i, B_i \rangle$ (resp. $\langle s, o' \rangle$), we would be able to reassign clients $j \in N_S(A_i) \cap N_O(o)$ (resp. $N_S(s) \cap N_O(o)$) to the facility $s' \notin A_i$ (resp. $s' \neq s$) that serves $\pi(j)$ in S.

The swaps defined above together satisfy the following properties:

1. Each facility in O is swapped-in to extent exactly 1.
2. Each facility in S is swapped-out to extent at most $(p+1)/p$.
3. If a swap $\langle A, B \rangle$ is considered, $capture(A) \subseteq B$.

Recall that in the single swap analysis, we used the fact that each facility in S was getting swapped-out at most twice, and upper bounded the second term of equation(3) by $2\sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 4 \cdot cost(O)$. We can now make use of the fact that each facility in S is swapped-out to the extent at most $(p+1)/p$, and upper bound the cost by $(p+1)/p \sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 2((p+1)/p)cost(O)$. This gives us an approximation bound of $3 + 2/p$.

3.5 Tight example

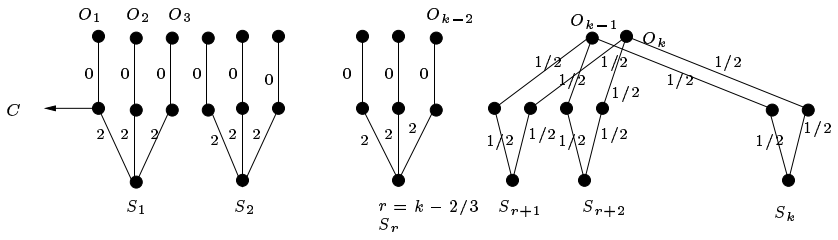

Figure 9: Tight example for the 2-swaps. The same example can be generalized to p-swap.

In Figure 9, we show an instance where a locally optimum solution, with respect to the 2-swap heuristic, has cost 4 times the cost of the global optimum. The locally optimum solution is given by $\{s_1, s_2, \ldots, s_k\}$, and the optimum solution is given by $\{o_1, o_2, \ldots, o_k\}$. It is easy to verify that we can not decrease the cost by performing any 2-swaps. The cost of our solution is $\frac{8k-10}{3}$, and the cost of the optimal solution is $\frac{2k+2}{3}$. This ratio approaches 4 as k tends to infinity. The same example can be generalized to p-swaps. Hence our analysis of the locality gap is tight.

4 Uncapacitated facility location

In facility location problems, we are given costs $f_i \geq 0$ for opening the facilities $i \in F$. The uncapacitated facility location problem is to identify a subset $S \subseteq F$ and to serve the clients in C by the facilities in S such that the total facility cost plus the total service cost is minimized. That is, if a client $j \in C$ is assigned to a facility $\sigma(j) \in S$ then we want to minimize $cost(S) = \sum_{i \in S} f_i + \sum_{j \in C} c_{\sigma(j)j}$. As in k-median, for a fixed S, serving each client by the nearest facility in S, minimizes the service cost.

4.1 A local search procedure

We present a local search procedure for the metric uncapacitated facility location with a locality gap of 3. The operations allowed in a local search step are adding a facility, deleting a facility, and swapping facilities. Hence the neighbourhood structure $\mathcal{N}$is defined by

$$\mathcal{N}(S) = \{S + \{s'\} | s' \notin S\} \cup \{S - \{s\} | s \in S\} \cup \{S - \{s\} + \{s'\} | s' \notin S \wedge s \in S\} \tag{4}$$

As the number of neighbours to be checked at each local search step is polynomial, the algorithm can be run in polynomial time as described before.

Charikar and Guha [3] proved a locality gap of 3 for a local search procedure where the operation was of adding a facility and dropping zero or more facilities. Korupolu et.al. [14] considered the operations of adding, deleting and swapping a facility but could only prove a locality gap of 5.

4.2 The analysis

For any set of facilities $S' \subseteq F$, let $cost_f(S') = \sum_{i \in S'} f_i$ denote the facility cost of the solution S'. Also, let $cost_s(S')$ be the total cost of serving the clients in C by the nearest facilities in S'.

Lemma 4.1 (Service cost)

$$cost_s(S) \ \leq \ cost_f(O) + cost_s(O)$$

Proof. Consider an operation in which a facility $o \in O$ is added. Assign all the clients $N_O(o)$ to o. From the local optimality of S we get, $f_o + \sum_{j \in N_O(o)} (O_j - S_j) \ \geq \ 0$. Note that even if $o \in S$, this inequality continues to hold. If we add such inequalities for every $o \in O$, we get the desired inequality. ∎

Now, we analyze the facility cost $cost_f(S)$. As before, we assume that π is a 1-1 and onto mapping satisfying the property 3.1. In addition, we assume that if $|N_S(s) \cap N_O(o)| > \frac{1}{2}|N_O(o)|$ then for all $j \in N_S(s) \cap N_O(o)$ for which $\pi(j) \in N_S(s)$, we have that $\pi(\pi(j)) = j$. It is easy to see that such a mapping exists. Recall that a facility $s \in S$ is called good if s does not capture any o, that is, for all $o \in O$, $|N_S(s) \cap N_O(o)| \leq \frac{1}{2}|N_O(o)|$. The facility cost of good facilities can be bounded easily as follows(Figure 10). Consider an operation in which a good facility $s \in S$ is dropped. Let $j \in N_S(s)$ and $\pi(j) \in N_S(s')$. As s does not capture any facility $o \in O$, we have that $s' \neq s$. If we assign j to s', we get, for a good facility $s \in S$,

$$-f_s + \sum_{j \in N_S(s)} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \ \geq \ 0 \tag{5}$$

For bounding the facility cost of a bad facility $s \in S$ we proceed as follows. Suppose a bad facility s captures the facilities $P \subseteq O$. Let $o \in P$ be the facility nearest to s. We consider the swap $\langle s, o \rangle$. The clients $j \in N_S(s)$ are now assigned to the facilities in $S - s + o$ as follows.

1. Suppose $\pi(j) \in N_S(s')$ where $s' \neq s$. Then, j is assigned to s'. Let $j \in N_O(o')$. We have, $c_{js'} \leq c_{jo'} + c_{o'\pi(j)} + c_{\pi(j)s'} = O_j + O_{\pi(j)} + S_{\pi(j)}$ (Figure 11(a)).

2. Suppose $\pi(j) \in N_S(s)$. Let $j \in N_O(o')$. Then, by the property of the mapping π, the facility s captures the facility o' and hence $o' \in P$. The client j is now assigned to the facility o. From triangle inequality, $c_{jo} \leq c_{js} + c_{so}$. Since o is nearer to s than o' is, $c_{so} \leq c_{so'} \leq c_{js} + c_{jo'}$. Therefore, $c_{jo} \leq c_{js} + c_{js} + c_{jo'} = S_j + S_j + O_j$(Figure 11(b)).

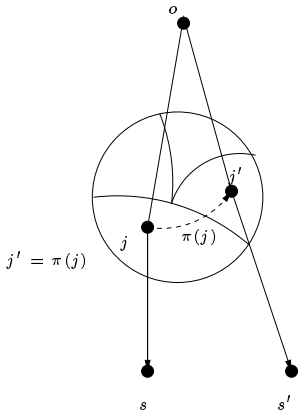

Figure 10: Bounding facility cost of a good facility s.

Thus for the swap $\langle s, o\rangle$ we get the following inequality.

$$f_o - f_s + \sum_{\substack{j \in N_O(o),\\ \pi(j) \in N_S(s)}} (O_j - S_j) + \sum_{\substack{j \notin N_O(o),\\ \pi(j) \in N_S(s)}} (S_j + S_j + O_j - S_j) + \sum_{\pi(j) \notin N_S(s)} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \;\geq\; 0 \tag{6}$$

Now consider an operation in which a facility $o' \in P - o$ is added(Figure 11(c)). The clients $j \in N_O(o')$ for which $\pi(j) \in N_S(s)$, are now assigned to the facility o' and this yields the following inequality.

$$f_{o'} + \sum_{\substack{\pi(j) \in N_S(s),\\ j \in N_O(o')}} (O_j - S_j) \;\geq\; 0 \qquad \text{for each } o' \in P - o \tag{7}$$

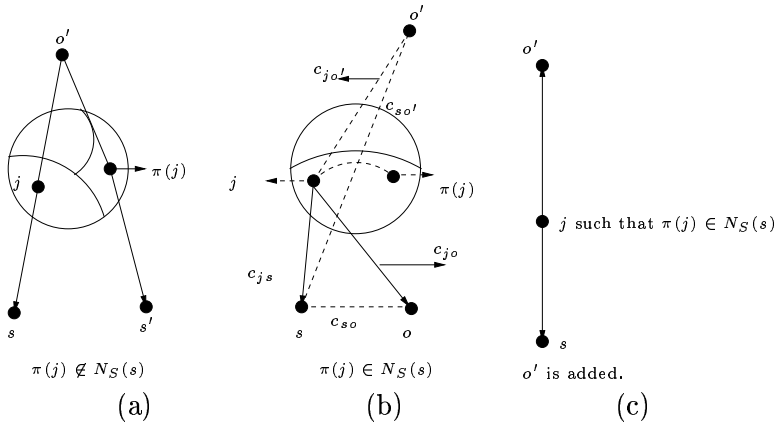

Figure 11: Bounding the facility cost of a bad facility s. (a), and (b) show reassignment when s is dropped, and (c) shows reassignment when o' is added.

Adding inequality (6) with inequalities (7) one for each $o' \in P - o$, we get, for a bad facility $s \in S$,

$$\sum_{o' \in P} f_{o'} - f_s + 2 \sum_{\substack{j \in N_S(s), \\ \pi(j) \in N_S(s)}} O_j + \sum_{\substack{j \in N_S(s), \\ \pi(j) \notin N_S(s)}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \geq 0 \tag{8}$$

Now, if we add the inequalities (5) for all good facilities $s \in S$ together with the inequalities (8) for all bad facilities s, we get, $cost_f(O) - cost_f(S) + 2 \cdot cost_s(O) \geq 0$. This proves the following lemma.

Lemma 4.2 (Facility cost)

$$cost_f(S) \leq cost_f(O) + 2 \cdot cost_s(O)$$

Combining Lemmas 4.1 and 4.2, we get the following result.

Theorem 4.3 *The local search procedure for the metric uncapacitated facility location problem with the neighbourhood structure $\mathcal{N}$ given by, $\mathcal{N}(S) = \{S + \{s'\} | s' \notin S\} \cup \{S - \{s\} | s \in S\} \cup \{S - \{s\} + \{s'\} | s' \notin S \wedge s \in S\}$ has a locality gap 3.*

The algorithm described above extends very simply to the case when the clients $j \in C$ have arbitrary demands $d_j \geq 0$ to be served. Using standard scaling techniques [3] our algorithm can be improved to achieve a $1 + \sqrt{2} \approx 2.414$ approximation.

4.3 Tight example

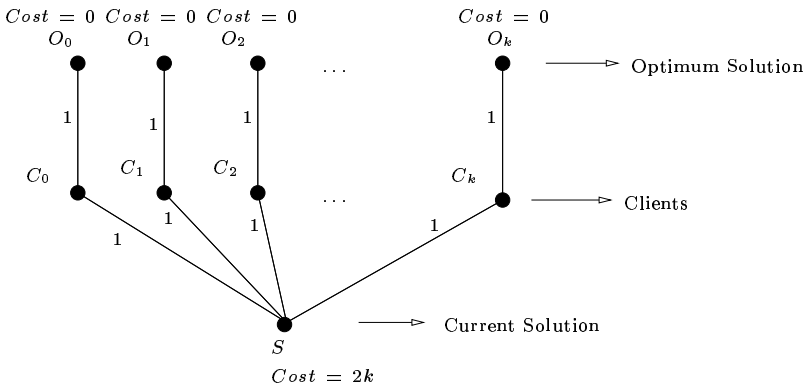

Figure 12: Tight example for uncapacitated facility location algorithm.

In Figure 12, we show an instance where a local optimum has cost 3 times the cost of the global optimum. The locally optimum solution consists of a single facility s. The optimum solution consists of $\{o_0, o_1, \ldots, o_k\}$. Clearly, we cannot delete the facility s. It is easy to verify that we can not decrease the cost of our solution by either adding any facility from the optimum, or by any swap which involves bringing in a facility from the optimum and deleting s. The cost of current solution is $3k + 1$, while the cost of the optimum solution is $k + 1$. Hence our analysis of the algorithm is tight.

5 The capacitated facility location problem

In the capacitated facility location problem, along with the facility costs $f_i \geq 0$, we are given capacities $u_i > 0$ for each $i \in F$. We can open multiple copies of a facility i. Each copy incurs a cost f_i and is capable of serving at most u_i clients. Note that the capacities u_i may be *different* for different facilities i. The problem is to identify a multi-set S of facilities and to serve the clients in C by the facilities in S such that the capacity constraints are satisfied and the total facility cost plus the total service cost is minimized. If a client $j \in C$ is assigned to a facility $\sigma(j) \in S$ then we want to minimize $cost(S) = \sum_{i \in S} f_i + \sum_{j \in C} c_{\sigma(j)j}$. Now, for a fixed S, in order to minimize the service cost, we solve a min-cost flow problem. The clients $j \in C$ send unit amount of flow to the facilities in S such that the capacity constraints are satisfied. Such a min-cost flow can be computed efficiently.

In the remainder of this section we let S and O be the multi-sets of the facilities opened in the output and optimum solutions respectively.

5.1 A local search algorithm

In this section, we prove a locality gap of at most 4 on a local search procedure for capacitated facility location problem. The operations allowed at each local search step are adding a facility $s' \in F$ or dropping a subset of the open facilities, $T \subseteq S$, and opening l new copies of a facility $s' \in F$. We require that l is sufficiently large so that the clients $j \in N_S(T)$ can be served by these new copies of s', that is, $l \cdot u_{s'} \geq |N_S(T)|$. So, the neighbourhood structure $\mathcal{N}$is defined by

$$\mathcal{N}(S) = \{S + s' | s' \in F\} \cup \{S - T + l.\{s'\} | s' \in F \text{ and } T \subseteq S \text{ and } l \in \mathbf{Z}^+\} \tag{9}$$

Here, $l.\{s'\}$ represents l new copies of s'. As in the case of the uncapacitated facility location, we restrict this operation so that all clients in $N_S(T)$ are served by the facility s'. The cost of the new solution is now given by

$$cost(S) + l \cdot f_{s'} + \sum_{s \in T} \left(-f_s + \sum_{j \in N_S(s)} (c_{s'j} - c_{sj}) \right)$$

Given a facility $s' \in F$, we use the Procedure `T-Hunt` described in Figure 13 to find a subset $T \subseteq S$ of facilities. Here $m = |C|$ is the upper bound on the number of new copies of s' that we need to open. Dropping a facility $s \in T$ gives an extra $|N_S(s)|$ clients to be served by the new facility s'. A client $j \in N_S(s)$ where $s \in T$ now travels a extra distance of at most $(c_{s'j} - c_{sj})$. Thus, dropping a facility $s \in T$ gives a *saving* of $f_s - \sum_{j \in N_S(s)} (c_{s'j} - c_{sj})$. Due to the capacity constraints, a copy of s' can serve at most $u_{s'}$ clients. This motivates us to define the following `Knapsack` problem. For a facility $s \in S$, define $weight(s) = |N_S(s)|$ and $profit(s) = f_s - \sum_{j \in N_S(s)} (c_{s'j} - c_{sj})$. The oracle `Knapsack`$(W)$ returns a multi-set $T \subseteq S$ such that $\sum_{s \in T} weight(s) \leq W$ and $profit(T) = \sum_{s \in T} profit(s)$ is maximized.

It is interesting to note that since we are permitting any subset of facilities, T, from our current solution, S, to be dropped, the number of operations are exponential in $|S|$. However, by counting the change in cost due to each such operation in a specific way, we are able to give a polynomial time procedure (the procedure `T-hunt`) to identify admissible operations. It might be case that `T-hunt` is not able to identify any admissible operations, while there are operations, as defined by `op`, which are admissible. However, our analysis will work only with the assumption that `T-hunt` could not find admissible operations.

Procedure `T-Hunt`.

1. For $l = 1$ to m do,
2. $\quad T \leftarrow$ `Knapsack`$(l \cdot u_{s'})$.
3. $\quad$ If $cost(S) + l \cdot f_{s'} - profit(T) \leq (1 - \frac{\epsilon}{p(n,m)})cost(S)$, then return T.
4. return "no admissible swap".

Figure 13: A procedure to find a subset $T \subseteq S$ of facilities

5.2 The analysis

Lemma 5.1 *For any $T \subseteq S$ and any $s' \in F$, we have,*

$$\lceil |N_S(T)|/u_{s'} \rceil \cdot f_{s'} + \sum_{s \in T} |N_S(s)| \cdot c_{ss'} \;\geq\; \sum_{s \in T} f_s$$

Proof. The algorithm terminated with the output S. Hence for the solution S and for the facility s', the Procedure `T-Hunt` must have returned "no admissible swap". Hence,

$$\begin{aligned} & l \cdot f_{s'} - profit(T) \\ &= \; l \cdot f_{s'} - \sum_{s \in T} \left(f_s - \sum_{j \in N_S(s)} (c_{s'j} - c_{sj}) \right) \;<\; 0 \end{aligned}$$

But, for a client $j \in N_S(s)$, we have, $c_{s'j} - c_{sj} \geq c_{ss'}$. Therefore we have the lemma. ∎

As the output S is locally optimum with respect to additions, the Lemma 4.1 continues to bound the service cost of S. We restate the Lemma 4.1 here.

Lemma 5.2 (Service cost)

$$cost_s(S) \;\leq\; cost_f(O) + cost_s(O)$$

Now, we bound the facility cost of S. Consider a directed graph $G = (V, E)$ with lengths on edges, where,

$$V = \{v_s \mid s \in S\} \bigcup \{w_o \mid o \in O\} \bigcup \{sink\},$$

$$E = \{(v_s, w_o) \mid s \in S, o \in O\} \bigcup \{(w_o, sink) \mid o \in O\}$$

The lengths of (v_s, w_o) and $(w_o, sink)$ are c_{so} and f_o/u_o respectively. The cost of routing unit amount of flow along any edge is equal to the length of that edge. We want to simultaneously route $|N_S(s)|$ units of flow from each v_s to the *sink*. Refer to Figure 14.

Lemma 5.3 *We can simultaneously route $|N_S(s)|$ units of flow from each v_s to the sink such that the total routing cost is at most $cost_s(S) + cost_s(O) + cost_f(O)$.*

Proof. Consider the clients $j \in C$. If $j \in N_S(s) \cap N_O(o)$ then route one unit of flow along the path $v_s \rightarrow w_o \rightarrow sink$(Figure 15(a)). Triangle inequality implies, $c_{so} \leq S_j + O_j$. Also, for a facility $o \in O$, the routing cost on the edge $(w_o, sink)$ is $|N_O(o)| \cdot f_o/u_o \leq \lceil |N_O(o)|/u_o \rceil \cdot f_o$, which in turn

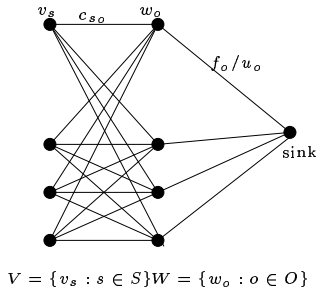

Figure 14: The flow graph

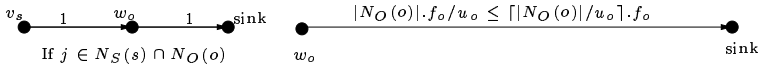

Figure 15: Routing on the flow graph.

is the contribution of o to $cost_f(O)$(Figure 15(b)). Thus, the routing cost of this flow is at most $cost_s(S) + cost_s(O) + cost_f(O)$. ∎

In the flow with the minimum routing cost, for each v_s, the flow of $|N_S(s)|$ units is routed along the shortest path from v_s to the sink. That is, along $v_s \rightarrow w_o \rightarrow sink$, where o is such that $c_{so} + f_o/u_o$ is minimized, ties being broken arbitrarily. For each $o \in O$, let $T_o \subseteq S$ denote the set of facilities s that route their flow via w_o. As this gives a minimum cost flow, from Lemma 5.3, we have,

$$\begin{aligned} & cost_s(S) + cost_s(O) + cost_f(O) \\ & \geq \sum_{o \in O} \sum_{s \in T_o} |N_S(s)|(c_{so} + f_o/u_o) \end{aligned} \tag{10}$$

Now, applying Lemma 5.1 to T_o and o, we get,

$$\lceil |N_S(T_o)|/u_o \rceil \cdot f_o + \sum_{s \in T_o} |N_S(s)| \cdot c_{so} \ \geq \ \sum_{s \in T_o} f_s$$

Hence,

$$f_o + |N_S(T_o)|/u_o \cdot f_o + \sum_{s \in T_o} |N_S(s)| \cdot c_{so} \ \geq \ \sum_{s \in T_o} f_s$$

Adding these inequalities for all $o \in O$, we get,

$$\begin{aligned} & \sum_{o \in O} f_o + \sum_{o \in O} \sum_{s \in T_o} |N_S(s)|(c_{so} + f_o/u_o) \\ & \geq \sum_{o \in O} \sum_{s \in T_o} f_s \ = \ cost_f(S) \end{aligned} \tag{11}$$

The inequalities (10) and (11) together imply

$$cost_f(S) \leq 2 \cdot cost_f(O) + cost_s(O) + cost_s(S)$$

This inequality together with Lemma 5.2 gives the following lemma.

Lemma 5.4 (Facility cost)

$$cost_f(S) \;\leq\; 3 \cdot cost_f(O) + 2 \cdot cost_s(O)$$

Combining Lemmas 5.2 and 5.4, we obtain the following result.

Theorem 5.5 *The local search procedure for the metric capacitated facility location problem with the neighbourhood structure defined in (9), representing the operations of adding a facility or deleting a subset of facilities and adding multiple copies of a facility has a locality gap of 4.*

Again using scaling techniques [3] the algorithm can be improved to obtain a $2 + \sqrt{3} \approx 3.732$ approximation. The tight example given in Section 4.3 for the uncapacitated facility location problem shows that a locally optimum solution for this problem can have cost 3 times the cost of the global optimum.

6 Conclusions and Open Problems

In this paper, we provided tighter analysis of local search procedures for the k-median and uncapacitated facility location problems. Our sharper analysis leads to a $3 + 2/p$-approximation algorithm for the k-median with a running time of $O(n^p)$. For capacitated facility location, when multiple copies of a facility can be opened, we introduce a new operation and show how a weaker version of this operation can be performed in polynomial time. This leads to a local search procedure with a locality gap of at most 4. We leave open the problem of obtaining tight bounds on the locality gap of this procedure. It would be interesting to identify such operations for other variants of facility location problems.

7 Acknowledgments

Arya, Garg, Khandekar and Pandit first published a preliminary version of this paper which did not include the results in Sections 3.3 and 3.4. After this version was distributed, Meyerson-Munagala and Arya-Garg-Khandekar-Pandit independently obtained the results in Sections 3.3 and 3.4. Garg and Khandekar would like to thank R. Ravi, Amitabh Sinha and Goran Konjevod for useful discussions.
